ABSTRACT

Nursing theories and models provide a framework for professionally organised nursing practice. One of the nursing theories that has an important place in nursing is ‘comfort theory’. Developed by Katharine Kolcaba, comfort theory offers a broad perspective on nursing. In this study, the problems experienced by a 15-year-old patient who was diagnosed with a right ovarian tumor and underwent salpingo-oophorectomy were assessed from the perspective of comfort. Our study aims to provide an example of the application of comfort theory in paediatric surgical clinics.

Keywords: Kolcaba, Comfort Theory, Surgery, Nursing Care

INTRODUCTION

The French word “fort” is derived from the Latin word “forting”. It is used synonymously with the word “comfort” in Turkish. According to the Turkish Language Association (TDK), the word “comfort” is defined as “It is a living situation or environment in which a person feels comfortable and peaceful, does not feel any physical and mental discomfort, and provides convenience”. The North American Nursing Diagnostic Association (NANDA) defines comfort as a feeling of psychological, physical or social well-being or comfort.3

The concept of “comfort” in nursing science has been discussed by many nurse theorists. Florence Nightingale was the first to mention comfort in nursing written sources.3 In Peplau’s theory, comfort is considered a basic need, while in Orlando’s theory, it is physical and mental comfort and the evaluation of situations that increase comfort. In Roy’s adjustment model, comfort is evaluated within the framework of psychological comfort. In Watson’s model, comfort is generally seen as a variable of interest.4

A theory is a system that provides meaning to concepts, renders them multidimensional, and establishes relationships between them. A theory is a set of concepts that are validated through the application of scientific methods to test observations and propositions.5 The “Comfort Theory,” developed by Katharine Kolcaba in 2003, enables a more systematic examination of the problems faced by care recipients and the development of The theory offers professional and user-friendly plans for nursing practice. According to the theory, comfort is defined as a response to problems arising from physical, socio-cultural, psycho-spiritual and environmental aspects at three levels: relaxation, refreshment and problem solving. Kolcaba examined the categorical structure of the two-stage theory, namely comfort level and comfort dimension.6,7 According to the comfort theory, comfort levels consist of three stages: relief, relaxation and superiority. Relief is the feeling of satisfaction when an individual is relieved from a state of distress. It is experienced as a result of the fulfillment of any need.8 Relaxation is a state of calm and peaceful existence. Transcendence is the state of being able to overcome problems by increasing one’s own power. This is possible when comfort needs are fully satisfied. In theory, comfort elements are defined in four stages: physical, socio-cultural, psychospiritual and environmental.3
1. In The Physical Dimension

Comfort requirements are related to bodily sensations. This encompasses physiological factors such as immune function, responses to illness, rest, nutrition, relaxation, nausea and vomiting.4

2. Sociocultural Comfort Requirements

It includes the individual’s social relationships, rituals, family traditions and beliefs. The sociocultural dimension of comfort encompasses interpersonal relationships and interactions with social institutions. The scope of this category also encompasses traditions, rules and legal regulations that regulate social and interpersonal relations.3

3. Comfort Needs In The Psycho-Spiritual Dimension

The psychospiritual dimension encompasses the cognitive, emotional and psychological components of comfort needs. This encompasses the individual’s mental, psychological and spiritual state (self-confidence, self-esteem, sexuality, meaning of life).6,8

4. Environmental Comfort Requirements

Environmental comfort needs are related to the external environment of the individual. This encompasses the impact of physical factors, such as light, temperature, smell, sound, colour and landscape, on individuals.3

In order to implement the comfort theory, it is first necessary to determine the comfort needs of the individual by utilising the categorical structure of the theory. The nurse should ascertain the comfort level of the individual prior to providing care. Subsequently, they should assess the patient’s physical, psycho-spiritual, environmental and sociocultural comfort needs with a holistic approach and apply nursing approaches to meet unmet needs. It is then necessary to re-measure the comfort level, evaluate the results of the expected increase in comfort and design a new plan appropriate to the situation.5,4 In this case report, the nursing care plan of a patient who presented to the emergency department with severe abdominal pain, vomiting and constipation was planned and evaluated according to the comfort theory.

Ethical Dimension

Before obtaining information from our patient, information about the research was given. Written and verbal consent was obtained.

Diagnostic Tool

In this study, patient-related data were collected using Kolcaba Comfort Theory and summarised below.

CASE

A 15-year-old girl presented to the emergency department with nonspecific symptoms including nausea, abdominal pain, weakness and restlessness which started two days ago. She additionally reported that her symptoms were accompanied by malaise and vomiting. Two days ago, she reported constipation and underwent an enema. Following the enema, she defecated, yet her complaint of pain intensified. In his past medical history, he reported experiencing intermittent abdominal discomfort and stated that he was taking analgesics. The patient’s height was 158 cm, weight was 70 kg, general condition was moderate, and colour was pale. No chronic disease was identified in the patient’s past medical history.

A physical examination revealed marked distension, tension, and diffuse tenderness in the lower abdomen on auscultation. The patient exhibited severe abdominal pain, and palpation of the right lower quadrant of the abdomen revealed an orange-sized mass with regular borders. Vital findings of the patient: temperature 37.0°C, pulse 110/min, respiration 27/min, SPO2 87 mmHg and blood pressure determined as 110/85 mmHg (Table 1).

Laboratory tests revealed the following results: hemoglobin: 11.2 g/dl, hematocrit: 34.0%, white blood cells (WBC): 14.12 mg/dl, sodium (Na): 130 mEq/l, C-reactive protein (CRP): 5.2 mg/l, lactate dehydrogenase (LDH): 325 units/l, and electrolyte values were within optimal limits. Liver and renal function tests were within the normal range, as were cardiac enzymes and the electrocardiogram (ECG). In the radiological examinations, the bladder contours were regular, the uterus was in a normal size and configuration in abdominal ultrasonography. The left ovary exhibited a normal nuclear structure, while a limited mass was identified in the right ovary. Oxygen was administered via a mask, and fluid resuscitation was initiated with an isotonic infusion at a rate of 200 cc/h. A blood group study was conducted to determine the necessity for transfusion, and two units of erythrocyte suspension were prepared.

All preoperative preparations were completed on time, and the patient was subsequently taken into surgery. During the surgical procedure, an incision is made between the lower and upper quadrants of the abdomen. The mass was excised from the surrounding tissues (Figure 1). During surgery, the ovary was found to be 5.5 cm in size and the ovary was detorsionised. Under the ovarian torsion was corrected by detorsion, the ovarian blood supply was insufficient (presence of ischaemic tissues). Necrotic tissues were also present around the tuba. There was haemoperitoneum, and the salpinx and ovary were resected (Figure 2). The other ovary was in natural appearance. Following the excision of the mass, the incisions were properly closed, and there was no intraoperative bleeding or complications (Figure 3).

The intraoperative rapid pathology examination revealed no evidence of malignancy, and the operation was completed. In the postoperative interview with the patient, she reported experiencing postoperative pain and expressed concerns about the risk of tumour recurrence.

The comfort level of the preoperative clinical presentation was measured as low as 1.58 on the General Comfort Scale (GCS). It was recognised that the patient’s comfort was low before the operation and that she had adjustment problems.

The General Comfort Scale (GCS) is a 48-item Likert-type scale developed by theorist Kolcaba in 1992. Its Turkish validity and reliability were determined by Kuguoğlu and...
Karabacak. The scale comprises 16 items pertaining to relief, 17 items pertaining to relaxation, and 15 items pertaining to coping. In the scale where positive and negative sentences are mixed, the score indicating a high degree of comfort in a positive sentence is 4, while the score indicating a high degree of comfort in a negative sentence is 1.3 The score that can be obtained from the scale can vary between 48 and 192. The obtained score is divided by the number of items on the scale, namely 48, in order to determine the comfort level, which ranges from a maximum score of 4 to a minimum score of 1.1

The general comfort scale is created using a classification structure consisting of three levels and four dimensions that form the theoretical components of comfort as a guide. This structure is used to define comfort-related requirements and to assess the situation in order to achieve the expected level of comfort with nursing. Interventions are planned to provide the desired comfort. The nursing diagnoses and interventions for the problems encountered by the patient are defined according to the classification structure of the comfort theory.

1: Physical Dimension
A patient who had experienced postoperative pain in the incision area was administered analgesics in accordance with the physician’s orders. Additionally, distraction techniques, such as watching movies and listening to music, were employed. It was observed that the patient exhibited a painful facial expression and a painful posture during walking. The patient’s pain was evaluated using the Visual Pain Scale. Prior to treatment, the patient’s pain score was recorded as 8, and following treatment, this decreased to 2. Furthermore, the patient indicated that her pain had been reduced in verbal communication.

Following surgery, the patient with constipation was informed of the potential for changes in excretory function, received comprehensive education in collaboration with the hospital nutritionist, and an appropriate diet list was created.

The patient was mobilised five hours after surgery and required assistance to transfer from the bed to a chair. A programme of passive range of motion exercises, slow and short activities, and rest periods was arranged in bed. The patient was encouraged to participate in their own care and rehabilitation, with the assistance of their parents. The patient’s daily activities were gradually increased, and he was included in daily self-care activities and was allowed to pass independently.

The patient was found to have respiratory dysfunction due to prolonged anaesthesia and immobility. The patient was supported to use deep breathing exercises and spirometry to breathe comfortably. The patient was supported to use the deep breathing exercises taught before the operation and to use spirometry. With these applications, the patient’s lung vital capacity was increased and optimal respiratory function was achieved (Table 2).

2: Psychological Dimension
The patient presents with a psychological issue pertaining to the deterioration of their individual identity, which is believed to be related to the postoperative changes that have occurred. It is observed that the patient exhibits behaviours such as hiding the surgical incision site, shaming, and avoiding discussion of the subject. The patient was informed that it was acceptable to accept her body image and was reassured. An appropriate setting was established, and the patient was afforded the chance to articulate her emotions and concerns.

The patient exhibits a fear of the future as a consequence of the surgical procedure she has undergone. The patient expressed concern about the possibility of the tumour recurring. It was determined that the patient exhibited a negative self-perception regarding her condition. The patient was encouraged to maintain eye contact and to express her feelings. It was emphasised that patients should be at peace with their body image and that their fears were, in fact, manageable. They were supported in seeking professional help.

The patient feels insecure because she thinks that her ovary was damaged during the removal of the tumour. She thinks that this situation will cause people to judge her in the future. She has general adjustment problems and ineffective coping. Both the patient and her family lack knowledge about basic health practices and health behaviour development. In order to deal with this situation, it is necessary to identify their concerns. The patient and her family were supported to ask for information. Information was given about the structure of the ovary and the post-operative status (Table 2).

3: Environmental Dimension
The patient was diagnosed with sleep disturbance due to the combined effects of postoperative pain, general hospitalisation, and frequent follow-up and treatment hours. Monitoring, treatment and care were provided in a manner that sought to minimise the impact on sleep patterns. The patient’s treatment plan was revised. The patient was kept awake during the day and provided with a comfortable night’s sleep (Table 2).

4: Socio-Cultural Dimension
It was observed that the patient exhibited social isolation problems as a consequence of the separation from her siblings and close friends and the unfamiliar environment in which she found herself. The patient was informed that the surgical site would heal and that it would not affect her social activities in the future. The patient’s needs were identified with the input of the parents and the patient was enabled to participate in physical, cognitive, emotional and social activities (Table 2).

DISCUSSION
The score that can be obtained from the scale can vary between 48-192. The obtained score is divided by the number of items of the scale, i.e. 48, to determine the comfort level ranging between a maximum score of 4 and a minimum score of 1.1

According to Kolcaba’s Comfort Theory, the evaluation of comfort levels after postoperative care is provided is important to demonstrate the effectiveness of the theory. During the patient’s preoperative clinical presentation, the
comfort level was measured as low as 1.58 on the General Comfort Scale (GCS). It was noticed that the patient’s comfort level was low before the operation and she had adjustment problems. On the 1st postoperative day, the comfort level was 1.50 4 hours after waking up from anaesthesia and before applying care within the framework of the comfort theory, while it was determined as 2.7 after starting to apply care within the framework of the comfort theory on the same day (at the 8th hour). On the 3rd postoperative day; this assessment, which is made in the first acute recovery process, is used to observe the effectiveness of the interventions made on the first day and the changes in the patient’s comfort, and the scale result was determined as 3.0. The 7th postoperative day is used to determine the progress in the patient’s recovery process, the effectiveness of pain management and the general comfort level of the patient, and the scale result was 3.2. This time period is especially critical for discharge planning and home care requirements.

In the study of Hughes and Whittemore (2021), the effect of nursing interventions based on Kolcaba’s Comfort Theory on the comfort levels of surgical patients was examined. The comfort levels of the patients were evaluated on the first and third postoperative days. The results of the study show that Kolcaba’s Comfort Theory is effective in increasing the comfort levels of patients and improving postoperative recovery processes when used in surgical nursing practices.9

In a randomised controlled study in which Aslan and Ünal (2020) evaluated the preoperative and postoperative comfort levels of surgical patients with nursing care interventions based on Kolcaba’s Comfort Theory, comfort levels were measured one day before surgery and on the first, third and seventh days after surgery. It shows that nursing interventions based on Kolcaba’s Comfort Theory have positive effects on the comfort and anxiety levels of surgical patients.10

In Salem and Salem (2020) study, the effect of nursing care based on Kolcaba’s Comfort Theory on the comfort levels of surgical patients in the postoperative period was evaluated. Measurements were made on the first, third and seventh days after surgery. It shows that Kolcaba’s Comfort Theory can be used effectively in the postoperative care of surgical patients and can increase the comfort levels of patients.11

Our study supports the results of the literature. In addition, the effectiveness of the theory was tested by looking at the comfort measurements before and after the theory-based nursing intervention on the 1st postoperative day. Comfort theory supports the physical and psychological well-being of patients and helps them recover faster and shorten their hospital stay.12 In addition, increasing patient satisfaction and decreasing complication rates offer important results in terms of improving the quality of care.

CONCLUSION

Consequently, the care plan for the patient who underwent salpingo-oophorectomy surgery due to an ovarian tumour was organised in accordance with Kolcaba’s Comfort Theory, and it was demonstrated that it was applicable in the field. It was demonstrated that an increase in comfort was achieved by adopting behaviours to improve well-being with the care provided according to the comfort theory.7,8 Based on the comfort theory developed by Kolcaba, nursing care can be shaped according to individual needs after nursing interventions to increase the comfort of the patient who has undergone surgical procedure.5,9,10,11 In this way, it is possible to contribute to the quality of life by providing the highest level of comfort to patients. It is thought that the use of comfort theory will be useful in seeing and responding to patient needs in a more systematic way.

Conflict of Interest Statement: There is no conflict of interest between the authors.

Financial Disclosure: There are no financial sources supporting the study.

ETHICAL DECLARATIONS

Informed Consent
Because the study was designed retrospectively, no written informed consent form was obtained from patients.

Referee Evaluation Process
Externally peer-reviewed.

Conflict of Interest Statement
The authors have no conflicts of interest to declare.

Financial Disclosure
The authors declared that this study has received no financial support.

Author Contributions
All of the authors declare that they have all participated in the design, execution, and analysis of the paper, and that they have approved the final version.
